11 **ABSTRACT:** The PCI diagnostic is an internal reference interferometer that creates an image of
12 absolutely calibrated electron density fluctuations integrated along the line of sight of the probing
13 light beam. While conventional PCI diagnostics installed on fusion experiments worldwide employ
14 light of wavelength equal to $10.59\ \mu\text{m}$, the same system using light at $1.55\ \mu\text{m}$ wavelength would
15 extend the spectral response in wave-number and frequency by factors of seven and over one hundred,
16 respectively, thereby potentially providing quantitative measurements of the internal structure of
17 density perturbations induced by either turbulent or radio-frequency waves, simultaneously covering
18 ion to electron gyro-radius scales up to the GHz frequency region. Based on a previously developed
19 bench-top $1.55\ \mu\text{m}$ PCI system, constraints to the design for such a diagnostic in fusion grade
20 devices are presented and compared to those faced with the conventional method.

21 **KEYWORDS:** Plasma diagnostics - interferometry, spectroscopy and imaging; Nuclear instruments
22 and methods for hot plasma diagnostics

26 **1 Introduction and motivation**

27 The Phase Contrast Imaging (PCI) method is an optical technique that converts phase shifts induced
28 on the wavefront of probing light travelling through a transparent medium into amplitude variations
29 at the image plane, where they can be imaged by suitable arrays of detectors. Invented in the
30 1930s by F. Zernike [1], who proved its superior sensitivity compared to competing methods used
31 in cellular microscopy, it was first applied to plasmas in the late 1960s [2] before being brought to
32 experiments worldwide on magnetically confined plasmas [3–12]. The high sensitivity of the PCI
33 method is enabled by the fact that it is an interferometer for which both the test and the reference
34 legs travel through the object. In the case of probing light frequency much higher than any plasma
35 frequency and for spatial inhomogeneities larger than the probing light wavelength, the Raman-
36 Nath regime [13] applies and the plasma behaves as a transparent object that induces phase shifts
37 proportional to the probing light wavelength and the electron plasma density integrated along the
38 probing beam line of sight. The total phase shift ϕ can be decomposed into a contribution given
39 by the stationary plasma density $\phi_0(\mathbf{x})$ and that due to fluctuations $\tilde{\phi}(\mathbf{x}, t)$, which is usually much
40 smaller than the former. The probing light electric field E_0 becomes equal to

$$E_{tot}(\mathbf{x}, t) = E_0 e^{i\phi(\mathbf{x}, t)} = E_0 e^{i\phi_0(\mathbf{x})} e^{i\tilde{\phi}(\mathbf{x}, t)} \simeq E_{\phi_0} [1 + i\tilde{\phi}(\mathbf{x}, t)], \quad (1.1)$$

41 so that the total electric field, E_{tot} , is composed of the reference beam, E_{ϕ_0} , and a $\pi/2$ phase shifted
42 test beam that has interacted with the fluctuating plasma density, $E_{\phi_0} i\tilde{\phi}$. The PCI method employs
43 the fact that the two legs propagate at finite angles with respect to each other and separates them in a
44 suitable focal plane of the imaging system. An additional $\pi/2$ phase shift is then applied by having
45 the reference beam impinge onto an appropriately size *groove*, of power reflectivity ρ , dug in an
46 otherwise flat optical component called *phase plate*. The *invisible* phase shifts are thereby made
47 *detectable* as variations in brightness and, to first order in the perturbed phase, can be expressed by
48 relation

$$|E(\mathbf{x}_\perp, t)|^2 \simeq \rho |E_{\phi_0}|^2 [1 \pm 2\tilde{\phi}(\mathbf{x}_\perp, t)/\sqrt{\rho}]. \quad (1.2)$$

49 Equation 1.2 shows that the sensitivity of a PCI system is a factor $2/\sqrt{\rho}$ higher than that of a
50 comparable homodyne interferometer operated in optimal detection mode, i.e. with the two legs
51 exactly out of phase, with other parameters being equal.

52 **Motivation for a near infra-red (NIR) PCI system** While a shorter probing wavelength reduces
53 refraction effects and more easily satisfies the low scattering angle approximation and the Raman-
54 Nath regime, optical aberrations and the quality of optical components have less of an impact
55 on the image at longer probing wavelength. Additionally, the focal spot of a given focusing optic
56 increases at increasing wavelength, which eases manufacturing tolerances on the width of the groove
57 and reduces the power density of the reference beam therein. PCI systems installed on magnetic
58 fusion devices worldwide employ CO₂ lasers oscillating on the 10.59 μm wavelength, which is a
59 compromise choice of the requirements above.

60 The probing wavelength plays a major role in determining the wave number and frequency spectrum
61 of plasma fluctuations that the system is able to resolve. Indeed, the fact the light should not be
62 clipped by any of the optics sets the upper limit to the scattering angle at which the test beam
63 propagates with respect to the reference beam. By lowering the probing wavelength from 10.59 μm to
64 1.55 μm allows one to resolve larger wave numbers, use smaller optics and/or cope with longer beam
65 paths. The frequency bandwidth is given by the rise time of the detectors. A 10.59 μm system uses
66 arrays HgCdTe detectors that are cryogenically cooled to minimize noise due to thermally excited
67 current carriers. As a result, the 3dB point is usually located at frequencies less than one or a
68 few MHz, depending on whether the detectors are operated in the photoconductive or photovoltaic
69 regime. The study of faster phenomena therefore requires the use of optical heterodyning techniques
70 requiring dedicated hardware components, careful alignment through the laser intensity modulator
71 as well as prior knowledge of the frequency of the wave to be measured. A 1.55 μm system uses
72 InGaAs arrays of detectors whose 3dB point is, depending on the size of the element, in the range
73 30 MHz to 1000 MHz, thereby increasing the bandwidth by up to three order of magnitude of
74 that of 10.59 μm systems and reducing overhead maintenance costs thanks to room temperature
75 operation, especially in future devices where recirculating liquid nitrogen circuits would have to
76 be designed and operated due to restricted access to the torus hall. Although the signal amplitude
77 linearly decreases with shorter probing light wavelength, the SNR does not degrade thanks to the
78 fact that, when compared to cryogenically cooled HgCdTe detectors, InGaAs detectors feature
79 a two order of magnitude higher normalized detectivity D^* and a larger saturation power, which
80 significantly lower detector and shot noise. Additionally, general optical components such as lenses,
81 beamsplitter, waveplates or modulators are readily available in the NIR and at lower cost than their
82 MIR counterparts.

83 **2 Design considerations**

84 The design of an imaging system aimed at detecting the spatio-temporal evolution of turbulent
85 structures in fusion devices heavily depends both on the beam path length and on the intensity of the
86 magnetic field that is used to confine the plasma. Based on the ITER plant layout, in future devices
87 we assume a roundtrip path 100 m long. In order to frame the problem at order-of-magnitude level,
88 we consider confining magnetic field between 3 T and 8 T, with the lower value being either the
89 edge/core of a mid/low-field device and the higher value the core of a high field device, and plasma
90 energies ranging between 0.2 keV and 10 keV. Conventional PCI systems employ light beams with
91 a diameter $2w_0$ of 5 cm to 10 cm, so that the minimum wave number resolved by the system is in
92 the vicinity of $\Delta k \simeq \pi/w_0 \simeq 1 \text{ cm}^{-1}$. In present experiments, depending on plasma parameters,

93 this value approaches the bulk of ion Larmor radius scale fluctuations, that are predicted to usually
 94 peak around $k_y \rho_D \simeq 0.3$. If the diagnostic is to capture the long wavelength limit it should have a
 95 resolution $\Delta k \simeq 0.1/\rho_D$ which, for the plasma parameters above, is in the range 170 m^{-1} to 25 m^{-1} .
 96 Considering the highest wave number limit, true electron scale fluctuations $k_y \rho_e \simeq 1$ translate to
 97 a high resolution in the range 104.000 m^{-1} to 15.000 m^{-1} . In view of the small Larmor radii in
 98 machines at relatively high field, one might use a smaller than usual beam size in the plasma in
 99 order to maintain high power on the detectors and small sized optics. This approach would be eased
 100 for $1.55 \mu\text{m}$ systems, for which the Rayleigh distance for a 1 cm radius beam waist exceeds 200 m.
 101 In a $10.59 \mu\text{m}$ system such a distance would be 30 m long, i.e. probably shorter than what the beam
 102 path length will be in future devices, thereby possibly requiring one to insert intermediate optics
 103 along the beam path.

104 **Refraction from the plasma** A $10.59 \mu\text{m}$ probing wavelength is short enough to guarantee
 105 negligible refraction from the plasma in present experiments. Even in the case of a high density
 106 device such as ITER, predictions for the toroidal interferometer-polarimeter diagnostic expect
 107 negligible refraction as long as the line averaged electron plasma density is maintained below
 108 a few 10^{21} m^{-3} [14]. Refraction of a probing light beam travelling entirely in the low field
 109 side region of a toroidal device, along any direction, can be treated with reasonable accuracy in
 110 spherical geometry. In this case, for a parabolic density profile $n(r) = n(0)[1 - (r/a)^2]$ with a
 111 being the plasma minor radius, Bouger's law applies and the maximum refraction angle is given
 112 by $\theta_{max} = \arcsin[\omega_{pe}(0)^2/\omega^2]$ [15]. Since, especially in the case of long beam paths, active
 113 positioning stabilization systems can compensate only small refraction angles, the equation for
 114 θ_{max} implies that, by reducing the probing wavelength from $10.59 \mu\text{m}$ to $1.55 \mu\text{m}$, the maximum
 115 allowable density for negligible refraction increases by almost a factor of fifty to reach 10^{23} m^{-3} ,
 116 above levels currently envisioned for disruption mitigation techniques.

117 **Depth of field** The longitudinal resolution at the object plane δz , or depth of field, is given by
 118 imposing that the maximum wave-number resolved by the system k_{max} is such that $k_{max}^2/k_0 \delta z \leq 1$,
 119 a condition that is more easily satisfied at shorter probing wavelength. In the case of ion scale
 120 fluctuations, i.e. $k_y \rho_D \simeq 0.1$, and for plasma parameters previously considered, the depth of field
 121 at the object plane is in the range 0.27 km to 13 km at $1.55 \mu\text{m}$ vs 40 m to 2000 m at $10.59 \mu\text{m}$. For
 122 true electron scale fluctuations, i.e. $k_y \rho_e \simeq 1$, the depth of focus reaches values of at least a few
 123 centimeters only for the $1.55 \mu\text{m}$ system in low to moderate field plasmas and for energies larger
 124 than a few keV, i.e. in the core region, while it is at the mm or sub-mm level in all other cases.
 125 Integration lengths of a few centimeters can be found at best using PCI systems for which the probing
 126 beam propagates at small angles with respect to the confining magnetic field lines, where spatial
 127 resolutions down to a few % of the normalized minor radius are achievable [8]. Let us consider a
 128 beam propagating along the tangential direction, aimed in such a way that the tangency point with
 129 the magnetic surface is at normalized radius $r/a = 3/4$, which is where most of the core turbulence
 130 is usually localized. The integration length is therefore equal to $L_z = 2\sqrt{(R_0 + a)^2 - (R_0 + 3/4a)^2}$,
 131 where R_0 is the centroid of the plasma flux surfaces and a the minor radius. Considering the case
 132 of $R_0/a = 3/2$ and $R_0/a = 3$, yields $L_z = 2.2a$ and $L_z = 2.8a$, respectively. Assuming a 5% radial
 133 resolution, the integration length reduces to $L_z = 2\sqrt{(R_0 + 3/4a + \delta r)^2 - (R_0 + 3/4a)^2} = [a, 1.2a]$

134 for spherical and standard aspect ratio tokamaks, respectively. When accounting for an actual
 135 equilibria and, optionally, a slant propagation angle of the light beam with respect to the horizontal
 136 plane of the machine, the values above can vary by up to 30%. Given the above, the Raman-nath
 137 regime in the core of a high field device imposes $k_{max}\rho_e$ of the order of 0.03 and 0.1 for the
 138 10.59 μm and 1.55 μm systems, respectively. While a relatively long integration length is beneficial
 139 to increase the signal-to-noise ratio, when the depth of field is shorter than the integration length the
 140 Raman-Nath regime no longer applies and the Bragg regime is needed to interpret the measurements.
 141 However, in case the investigation does not require the system to reveal channel-to-channel phasing
 142 information that could be important to untangle the physics at play, it is still possible to infer the
 143 power spectrum in defocused systems and it is often done in present day experiments. A brief
 144 discussion of optical aberrations is warranted. Although working at reduced probing wavelength is
 145 beneficial for aberrations because of smaller scattering angles and smaller optics, a given aberration
 146 is more critical to the image quality at shorter probing wavelength. Considering the highest wave
 147 numbers compatible with the Raman-Nath regime as derived above, we consider a design made of
 148 three lenses after the phase plate that are used to provide a transverse magnification equal to 0.1.
 149 Including third order Seidel aberrations, at the image plane of the 10.59 μm system we estimate
 150 a 90 μm wide blur and 3% as optical path difference normalized to the probing wavelength. For
 151 the 1.55 μm system, despite the fact that the maximum wave number it can resolve is almost three
 152 times as large, the scattering angle is about three times smaller, resulting in an estimated 50 μm
 153 wide blur and 5% as optical path difference normalized to the probing wavelength. The impact of
 154 surface inaccuracies of various optics was estimated by including ten mirrors, two vacuum interface
 155 windows and five lenses. Surface accuracy, expressed in units of 632 nm per inch peak-valley,
 156 was specified to 0.1 for all mirrors, 1/4 for NBK-7 lenses as well as for ZnSe lenses and vacuum
 157 interface windows, while BaF₂ windows were assigned a value of unity. A conservative estimate
 158 for the surface of the optical elements illuminated by ray bundles originating from the plasma yields
 159 an optical path distance that, normalized to the probing wavelength, is equal to 1.5% and 8%,
 160 respectively, for the 10.59 μm and 1.55 μm systems.

161 **Focal spot** Reducing the wavelength of the probing light beam is disadvantageous to PCI systems
 162 because the depth and the width of the phase plate groove must be reduced by the same factor. While
 163 the requirements for the depth were met in the prototype 1.55 μm PCI system [16], those given by
 164 the width might be of higher concern. Indeed, while a 2 m focal length focuses a $2w_0 = 10$ cm wide,
 165 $M^2 = 1.1$, 10.59 μm laser beam on a spot size $2w_f = \frac{4M^2\lambda_0 f}{\pi 2w_0} \simeq 300$ μm , such a value becomes less
 166 than 50 μm with an equivalent system using 1.55 μm wavelength light. This, besides increasing the
 167 power density on the phase groove by about a factor of 50, translates into much stricter requirements
 168 regarding the uniformity of the phase groove. More specifically, while a focal spot on the phase
 169 plate is allowed to move by tens of microns with negligible impact on the signal quality in typical
 170 10.59 μm PCI systems, on an equivalent 1.55 μm system such a perturbation cannot exceed a few
 171 micrometers. This value sets the stabilization requirements for the feedback system, as well as
 172 on the uniformity of the groove width along its length because the feedback stabilization system
 173 will generally allow some level of movement along that direction. While such a requirement is
 174 relaxed by lengthening the focal length of the optics used to focus the beam on the phase plate,
 175 increasing this by the ratio of the two probing wavelengths, $10.6/1.55 \simeq 7$, will result in the need

176 for a focusing optics large enough to collect the entire beam and with a focal length in the range
 177 15 m to 20 m, which is expensive if at all possible. A solution involves using relay focusing optics,
 178 all having relatively short focal lengths that are commercially available, to create a system having
 179 the desired effective focal length. Let us consider a system composed of two focusing optics spaced
 180 by a distance l_1 . The formalism of the Ray Transfer Matrix Analysis [17] can be used to derive the
 181 distance r from and the angle of propagation θ with respect to the optical axis of any ray at distance
 182 l_2 after the second lens, given the corresponding values before the first focusing optics. In order to
 183 simplify the equations we will assume that the two optics have the same focal length f , for which

$$\begin{bmatrix} A , B \\ C , D \end{bmatrix} = \begin{bmatrix} \frac{f^2+l_1l_2-f(l_1+2l_2)}{f^2} , l_1 + l_2 - \frac{l_1l_2}{f} \\ -\frac{2f-l_1}{f^2} , 1 - \frac{l_1}{f} \end{bmatrix}.$$

184 The C element indicates that the spot-size on the phase plate can be made larger by making l_1 slightly
 185 longer than $2f$, in such a way as to have an effective focal length equal to $f_{\text{eff}} = f^2/(l_1 - 2f)$. Not
 186 only this allows a 1.55 μm system to have wider phase grooves, but deviations of the groove width
 187 from the nominal value can be compensated by slightly displacing the two focusing optics. More
 188 specifically, the complex beam parameter q transforms as $1/q = (C + D/q_0)/(A + B/q_0)$ and its
 189 value on the phase groove can be calculated at focus by using the ABCD matrix given the value q_0
 190 at the object plane, located a (large) distance l_0 from the first focusing optics. By letting l_1 exceed
 191 twice the focal length f by a (small) quantity x , i.e. $l_1 = 2f + x$, choosing l_2 such that the system
 192 is at focus, the ABCD matrix reduces to

$$\begin{bmatrix} A , B \\ C , D \end{bmatrix} = \begin{bmatrix} 0 , -\frac{f^2}{x} \\ \frac{x}{f^2} , -x\frac{l_0-f}{f^2} - 1 \end{bmatrix}.$$

193 Since the Rayleigh distance for 1.55 μm systems is large, to very good accuracy we can consider the
 194 expanded beam at the object plane as flat, i.e. $1/q_0 = -i/z_R$. As a result, the width of the Gaussian
 195 beam at focus then becomes equal to

$$w(\text{focus}) = \frac{\lambda_0 f^2}{\pi w_0 x}, \quad (2.1)$$

196 which shows that, as displayed in figure 1, if the displacement parameter x is sufficiently small
 197 compared to the focal length f , the waist at the focus can be significantly larger than 50 μm .

198 **Feed-back stabilization** Internal reference interferometers are insensitive to mechanical vibra-
 199 tions as long as the trajectory of probing light beam does not deviate from its design path. When
 200 optics are mounted on any vibrating component, the focused beam might move away from the phase
 201 groove thereby zeroing the signal. Current PCI systems employ active stabilization system using
 202 small galvo mirrors that adjust in real time the position of the beam on the phase plate by making
 203 an image of the focal plane on an array of detectors in a quadrant layout configuration. Systems
 204 employing light at 1.55 μm wavelength can benefit from the availability of duo-lateral position
 205 sensing detectors (PSD). Indeed, as opposed to quadrant positioning photodiodes that require the
 206 beam light to overlap in all quadrants, the performance of lateral effect sensors is independent of
 207 beam shape and size and only requires light to impinge on their sensing area. Additionally, while

Figure 1. Gaussian width at focus for a two-lens system, of 1 m focal length each, that focuses a 4 cm wide gaussian beam of 1.55 μm wavelength.

208 the response of quadrant detectors is linear only for small displacements, that of PSD is linear over
 209 the entire range of the sensing area which can be as large as 10 mm. Although PSD in the visible
 210 spectral region could be used by 10.59 μm systems, they yielded inadequate performance in early
 211 tests due to power flicker noise from the HeNe laser used for alignment as well as ambient light
 212 disturbance [18]. Both of these noise sources are expected to play a much smaller impact on a
 213 1.55 μm system using scientific grade Er laser and PSD sensitive only around 1.55 μm wavelength.
 214 As for quadrant detectors, the accuracy of the measurements can be negatively affected by the
 215 presence of ghost beams due to secondary reflections from other optics. This is due to the fact PSD
 216 only measure the centroid of the light impinging on the sensor, which causes large errors when two
 217 beamlets are present on the sensor surface. Besides using wedged optics to deviate the trajectory
 218 of the ghost beam from that of the main beam and eventually blocking it, this problem can be
 219 alleviated by using CCDs that allow to distinguish the main and the ghost beams by measuring
 220 signal amplitude of the two light spots, at the expense of complexity and frequency response of
 221 the system. The frequency bandwidth is about 15 kHz, which is comparable to that on existing
 222 10.59 μm systems and is adequate for compensating vibrations that, on typical fusion devices, are
 223 limited to a few hundred Hertz. In a typical compensation circuit used for PCI systems, such as that
 224 installed on the DIII-D tokamak, the dominant uncertainty term in the position of the beam light on
 225 the phase groove is given by the uncertainty in the positioning sensor [18]. The spatial resolution
 226 of PSD is specified to be less than 100 nm, depending on their size, which has to be convoluted to
 227 the spatial power distribution of the light beam. Considering scientific-grade lasers and accounting
 228 for an larger than unity magnification between focal plane and PSD, this would meet the design re-
 229 quirements when the focal spot on the phase plate is widened to a few hundreds of microns. Other
 230 sources of errors due to the electrical circuit and the scanners are expected to be similar to those
 231 in current systems, i.e. negligible. When compensating for vibration at the focal plane, the image
 232 plane undergoes spatial shifts that might compromise the measurements. If we consider a focusing
 233 optics at distance l_0 from the object plane and a vibrating mirror at distance D , either positive or
 234 negative, from the object plane, the uncompensated shift at the image plane due to the vibration is
 235 equal to $DM\delta\theta$, where $\delta\theta$ is the perturbed direction of propagation of the light beam and M the
 236 transverse magnification of the system. Considering a feedback system with galvo mirrors located
 237 after the focusing optics and at distance d from the phase plate, then the correction to the propagation

238 in response to $\delta\theta$ is $F_0/d * \delta\theta$. At the plane corresponding to the position of the galvo mirror, the
 239 propagation direction is perturbed by the quantity $[1 - (L_0 + D)/F_0]\delta\theta$. By applying the correction,
 240 the perturbed propagation direction becomes equal to $\delta\theta_{galvo} = [1 - (L_0 + D)/F_0 - F_0/d]\delta\theta$.
 241 By propagating till the phase plate followed by a generic ABCD matrix representing the rest of
 242 optical systems till the image plane, we obtain that the image is shifted by an amount equal to
 243 $\delta r_{image} = M(F_0^2/d + D - F_0 + L_0)\delta\theta$, as was also derived by Coda [18]. Considering now a more
 244 general case of two mirrors mounted on the vessel, let us orient the reference frame such that the
 245 incident light beam propagates along direction $(\hat{x}, \hat{y}) = (1, 0)$, with the two mirrors oriented as
 246 $(\hat{x}, \hat{y}) = (-1, 1)/\sqrt{2}$ and $(\hat{x}, \hat{y}) = (-1, -1)/\sqrt{2}$, respectively, so that, in a vibration free environment,
 247 the outgoing light beam propagates along $(\hat{x}, \hat{y}) = (-1, 0)$ after undergoing two $\pi/2$ reflections on
 248 the two mirrors. Let us now consider small vibrations such that the beam undergoes perturbed
 249 reflections at angles $\pi/2 + \delta\theta_{1,2}$. By writing the two rotation matrices and expanding to second
 250 order, the outgoing direction of propagation is given by

$$\begin{bmatrix} \hat{x}_{out} \\ \hat{y}_{out} \end{bmatrix} = \begin{bmatrix} \delta\theta_1\delta\theta_2 - 1 + \delta\theta_1^2 - \delta\theta_2^2 & \delta\theta_1 + \delta\theta_2 \\ -\delta\theta_1 - \delta\theta_2 & \delta\theta_1\delta\theta_2 - 1 + \delta\theta_1^2 - \delta\theta_2^2 \end{bmatrix} \begin{bmatrix} 1 \\ 0 \end{bmatrix},$$

251 resulting in a leading order $\delta\theta_{out} = \arctan(\hat{y}/\hat{x})$ that is the first order sum of the individual
 252 perturbations. It can be shown that a similar reasoning holds if more vibrating mirrors are added.
 253 The root mean squared perturbation to the propagation direction of the beam is therefore much
 254 higher when there is significant correlation among the individual perturbations, e.g. when the
 255 entire fusion device tilts due to currents induced during a discharge ramp-up phase or a disruption.
 256 Considering that in next step devices $L_0 \gg F_0, D, F_0^2/d$, we can approximate $\delta y_{img} = ML_0\delta\theta$. By
 257 assuming $L_0 = 50$ m and overall $\delta\theta = 100 \mu\text{rad}$ produced by uncorrelated vibrations of N mirrors,
 258 we obtain that the apparent shift in the image is $M\sqrt{N}$ in units of centimeters. This translates in
 259 an unacceptable shift at the image plane that would be larger than the element separation along the
 260 array of detectors. In the case of a feedback system placed on the launching side of the optics table,
 261 such that the galvo mirrors are approximately located at distance l_0 before the plasma and vibrations
 262 induced at position $l_0 - D$, the feedback system would have to compensate for the actual $\delta\theta$ resulting
 263 from all the vibrations. The shift at the image plane is equal to $\delta y_{img} = M(D - L_0)\delta\theta$ which, in
 264 the case $L_0 - D \gg F_0^2/d$, is quantitatively similar to that for the case of the feedback located on the
 265 receiving side of the optics table. The obvious advantage of a feedback system on the launching side
 266 of the optics table is that it just needs to compensate $\delta\theta$, rather than $[1 - (L_0 + D)/F_0]\delta\theta$, which allows
 267 for a larger compensation frequency bandwidth. Given estimates above, we conclude that in future
 268 devices with substantial mechanical vibrations, PCI systems relying on vibrating optics will need
 269 a second feed-back position stabilizing system at the image plane. This applies to tokamaks when
 270 operated in pulsed mode, the requirements for tokamaks in steady-state operations and stellarators
 271 will probably be much looser. In the case of a strongly vibrating vessel, we envision a system on
 272 the launching side of the optics table to act on the phase plate, while the system compensating the
 273 image plane will act on light after is reflected by the phase plate, thereby not interfering with the
 274 first system. Given the large beam paths involved, the use of a stabilizing system for the phase plate
 275 on the receiving side of the optics table would likely entail stabilizing the laser beam on the galvo
 276 mirrors, which would successively stabilize the laser beam on the phase plate. In this case, the
 277 first system would have to be limited to a few Hz-bandwidth to compensate shifts due to vibrations

278 during the start-up of a plasma discharge and not interfere with the higher bandwidth system acting
279 on the phase plate. An additional system at the image plane would still be required.

280 **System cost** The cost of detectors, overhead maintenance of components as well as product
281 availability are the main dollar drive for the 1.55 μm system. The cost of a sixteen-channels
282 30 MHz detector is of the order of 1000 USD, which is about 5 – 10% the cost of a similar
283 1 MHz bandwidth photoconductive HgCdTe array used by 10.59 μm systems. If one were to use
284 photovoltaic elements to increase the frequency bandwidth to 10 MHz and be comparable to the
285 1.55 μm system, NRE costs would inflate the price by about 100 times, without guaranteeing product
286 quality standards typical for off-the-shelf components. The cost for large optical components is hard
287 to estimate because their size and number depends on the details of the optical design. It is certain,
288 however, that all the optics used to collect light before the phase plate can be smaller and/or fewer
289 in number thanks to the reduced scattering angle at shorter probing light wavelength. The cost of
290 small optics such as lenses, beamsplitters and wave-plates is reduced by 3 – 10 times, while BaF₂
291 vacuum interface windows do not offer significant cost savings of ZnSe counterparts. Duo-lateral
292 PSD cost about half the price as compared to HgCdTe quadrant detectors. The savings in optics and
293 position stabilizing system are approximately compensated by the higher cost of a 20 W to 50 W
294 scientific grade Er laser as compared to standard CO₂ counterparts.

295 **Combined PCI-interferometer** Using laser light in the near infrared region allows for consider-
296 able simplification of the hardware if one were to employ a combined PCI-interferometer. As was
297 demonstrated on DIII-D tokamak [19], by splitting the light beam coming from the plasma one can
298 build both a PCI and a Mach-Zehnder interferometer using the same port allocation, with the further
299 advantage of having a straightforward absolute calibration of the PCI system when the optical design
300 is such that the interferometer and the PCI responses are made to overlap in wave-number space. In
301 a 10.59 μm system, the reference beam of the interferometer should travel the same distance as the
302 plasma beam for phase matching conditions, unless the coherence length of the probing laser is long
303 enough to make the phase noise negligible. In a 1.55 μm system, the reference leg would instead be
304 sent to a compact fiber bundle, without the need for dedicated optics thus further reducing system
305 complexity and associated costs.

306 **Conclusions**

307 A Phase Contrast Imaging system using 1.55 μm probing light offers several advantages over
308 conventional 10.59 μm systems terms of wave number and frequency bandwidth of the system,
309 cost and availability of individual components as well as maintenance overhead. Technological
310 constraints on the depth of the phase groove can be met, while those on the width can be addressed
311 by dedicated optical design. Preliminary design work show that aberrations are not expected to be
312 detrimental to the image quality despite the reduced operating wavelength, while surface accuracy
313 of optical components might have a larger impact. Despite a lower signal cause by the shorter
314 probing wavelength, low noise InGaAs detectors offer similar SNR to the HgCdTe counterparts.
